Keywords: NH<sub>3</sub>-SCR CeO<sub>2</sub> Acidity Redox capability H<sub>2</sub>SO<sub>4</sub>

## ABSTRACT

The effect of acidity and redox capability over sulfuric acid-modified CeO<sub>2</sub> catalysts were studied for the selective catalytic reduction of NO<sub>x</sub> with NH<sub>3</sub> (NH<sub>3</sub>-SCR). The deposition of sulfate significantly enhanced the catalytic performance over CeO<sub>2</sub>. NO<sub>x</sub> conversion over  $4H_2SO_4/CeO_2$  at 230–440 °C was higher than 90%. The strong redox capability of CeO<sub>2</sub> could result in unselective NH<sub>3</sub> oxidation and decrease high temperatures catalytic activity and N<sub>2</sub> selectivity. The deposition of sulfate increased the acidity and weakened the redox capability, and then increased the high temperature NO<sub>x</sub> conversion and N<sub>2</sub> selectivity. An appropriate level of acidity also promoted the activity at 190–250 °C over ceria-based catalysts, and with further increase in the acidity, the SCR activity decreased slightly. Weak redox capability lowered the low-temperature catalytic activity. Excellent SCR activity requires a balance of acidity and redox capability on the catalysts.

## Introduction

Nitrogen oxides are important atmospheric pollutants, contributing to serious environmental problems (Bosch and Janssen, 1988; Qi et al., 2004). The selective catalytic reduction of NO<sub>x</sub> with NH<sub>3</sub> (NH<sub>3</sub>-SCR) over V<sub>2</sub>O<sub>5</sub>-WO<sub>3</sub>(MoO<sub>3</sub>)/TiO<sub>2</sub> has been widely applied to remove NO<sub>x</sub> (Bosch and Janssen, 1988; Busca et al., 2005). However, the vanadia-based catalysts still presented several disadvantages, such as the toxicity and volatility of V<sub>2</sub>O<sub>5</sub> species, the narrow operating temperature window, high conversion of SO<sub>2</sub> to SO<sub>3</sub> and low N<sub>2</sub> selectivity at high temperatures (Balle et al., 2009; Busca et al., 1998; Dunn et al., 1998; Zhu et al., 2018). Consequently, the development of new non-vanadia based catalysts with excellent catalytic performance is of great urgency.

Cerium oxide (CeO<sub>2</sub>) has attracted a lot of interests due to the excellent redox properties and strong oxygen storage capability (Boningari et al., 2015; Duan et al., 2018; Wang et al., 2015; Weng et al., 2016; Zhao et al., 2017). Some CeO<sub>2</sub>-based catalysts, such as CeO<sub>2</sub>-TiO<sub>2</sub> (Shan et al., 2012), CeWO<sub>x</sub> (Chen et al., 2011; Shan et al., 2015), Co-CeTi (Liu et al., 2017b) and Zr-CeVO<sub>4</sub> (Zhao et al., 2016), have shown good NH<sub>3</sub>-SCR performance. The acidity of CeO<sub>2</sub> catalysts was found to be significantly enhanced by the introduction of tungstate (Chen et al., 2010), niobate (Qu et al., 2013), and sulfate (Zhang et al., 2016a), and which then increased the catalytic activity. The enhanced catalytic performance over

<sup>\*</sup> Corresponding authors. E-mail: honghe@rcees.ac.cn, (Hong He), qcfeng@rcees.ac.cn. (Qingcai Feng).

 $H_3PO_4$ -modified CeO<sub>2</sub> was due to the reduction in redox ability and the increase in acidic strength (Yi et al., 2016). The interaction between phosphotungstic acid and CeO<sub>2</sub> contributed to excellent redox properties and favored the surface acidity of phosphotungstic acid-modified CeO<sub>2</sub> catalysts (Song et al., 2017). CeO<sub>2</sub> pretreated with different acids (HCl, HNO<sub>3</sub>, HAc, H<sub>2</sub>SO<sub>4</sub> and H<sub>3</sub>PO<sub>4</sub>) was studied, and the sample pretreated by H<sub>2</sub>SO<sub>4</sub> was found to exhibit the best catalytic performance (Yao et al., 2017). The 2.5 wt.% SO<sub>4</sub><sup>2</sup>/CeO<sub>2</sub> catalysts showed the highest catalytic activity and strong resistance to SO<sub>2</sub> and H<sub>2</sub>O (Zhang et al., 2016b). Based on the above discussion, it is noteworthy that the NH<sub>3</sub>-SCR activity over ceria-based catalysts could be improved by enhancing surface acidity. However, the relationship of SCR performance and the coupling of redox capability and acidity has not been investigated in depth for ceria-based catalysts.

In this study, acid modification of  $CeO_2$  was conducted to study the coupling of acidity and redox capability of ceriabased catalysts. The  $CeO_2$  catalyst was firstly synthesized via a hydrothermal route and then modified by  $H_2SO_4$  using an impregnation method. The  $xH_2SO_4/CeO_2$  catalyst showed excellent NH<sub>3</sub>-SCR activity and strong resistance to  $H_2O$  and SO<sub>2</sub>, due to the balance of acidity and redox capability.

## 1. Materials and methods

## 1.1. Catalyst synthesis

The CeO<sub>2</sub> sample was synthesized by a hydrothermal method. First we dissolved Ce(NO<sub>3</sub>)<sub>4</sub> and NaOH in deionized water, respectively and then mixed them to obtain a purple slurry. Subsequently it was transferred into a Teflon-lined stainlesssteel autoclave at 120°C and held there for 12 hr. The deionized water and anhydrous ethanol were used to wash the fresh precipitates for removing any possible ionic remnants. Finally, the sample was dried at 60°C overnight and calcined in static air at 550°C for 4 hr.

Sulfuric acid-modified CeO<sub>2</sub> catalysts were prepared *via* an impregnation route.  $H_2SO_4$  solutions with different concentrations were added to the CeO<sub>2</sub> carrier. After stirring, the mixtures were desiccated at 110°C overnight and calcined in static air at 500°C for 3 hr. The catalysts were designated as  $xH_2SO_4/CeO_2$ , where x = 1, 2 and 4 represent the  $SO_4^{2-}$  loadings of 7.5, 15 and 30 wt.% added in the process of preparation, respectively. The surface composition of ceria-based catalysts as determined by XPS is present in Table S1 in Supporting Information. Different amounts of sulfur existed in  $xH_2SO_4/CeO_2$  and sulfur mainly existed on the surface.

#### 1.2. Characterization

A Quantachrome Autosorb iQ2 automatic adsorption instrument was applied to measure Nitrogen adsorption/desorption isotherms at -196°C. The samples were degassed at 300°C for 5 hr prior to N<sub>2</sub> physisorption. Surface area and pore structure were determined by the BET equation in the 0.05–0.30 partial pressure range and the Barrett–Joyner–Halenda (BJH) method from the desorption branches of the isotherms, respectively.

Powder XRD measurements were performed by a PANalytical B.V. X'Pert Pro XRD diffractometer using Cu  $K\alpha$  radiation at

40 mA and 40 kV. The 20 data from 10 to  $80^{\circ}$  were recorded at  $8^{\circ}$ / min with the step size of  $0.07^{\circ}$ .

 $\rm H_2$ -TPR experiments were conducted using a Quantachrome ChemStar analyzer. The samples (100 mg) were pretreated in Ar flow (100 ml/min) at 400°C for 30 min and then cooled down to 30°C followed by Ar purging. The reduction temperature was raised to 900°C at 10°C/min in  $\rm H_2$  (5 vol%)/Ar (100 ml/min).

 $O_2\text{-}\text{TPD}$  experiments were carried out on Micromeritics AutoChem 2920 Chemisorption Analyzer. A 100 mg sample was pretreated in He flow at 300°C for 30 min. The sample was then saturated with 5%  $O_2/\text{He}$  (50 ml/min) for 1 hr at 30°C and purged with He flow for 40 min. Finally, the sample was heated to 1000°C at the rate of 10°C/min in He flow (50 ml/min). The outlet exhaust was detected by TCD.

X-ray photoelectron spectroscopy (XPS) measurements were carried out on a PHI Quantum 2000 Scanning ESCA Microprobe with a monochromatized microfocused Al X-ray source. All the binding energies were calibrated using C1s as the reference energy (C1s = 284.6 eV).

#### 1.3. In situDRIFTS studies

In situDRIFTS experiments were conducted on an FTIR spectrometer (Thermo Fisher Nicolet iS50) equipped with a Smart Collector and an MCT/A detector cooled by liquid nitrogen. The sample was pretreated in a flow of 20 vol.%  $O_2/N_2$  at 300°C for 30 min, then cooled down to 225°C, and subsequently purged with  $N_2$  for background collection. The reaction conditions were controlled as follows: 300 ml/min total flow rate, 500 ppm NH<sub>3</sub> or 500 ppm NO + 5 vol.%  $O_2$  and  $N_2$  balance. All spectra were recorded by accumulating 100 scans with a resolution of 4 cm<sup>-1</sup>.

#### 1.4. Activity tests

The NH<sub>3</sub>-SCR activity tests over the ceria-based catalysts (40– 60 mesh) were conducted in a fixed-bed quartz flow reactor. The inlet gases included 500 ppm NH<sub>3</sub> or/and 500 ppm NO, 5 vol.% O<sub>2</sub>, 100 ppm SO<sub>2</sub> (when used), 10% H<sub>2</sub>O (when used) and N<sub>2</sub> balance and GHSV 50,000 hr<sup>-1</sup>. The effluent gases, including NH<sub>3</sub>, NO, N<sub>2</sub>O and NO<sub>2</sub>, were analyzed by an FTIR gas analyzer (Thermo Fisher IGS).

## 2. Results

#### 2.1. Catalyst characterization

#### 2.1.1. BET and XRD results

The surface area and pore characterization results for ceriabased samples are shown in Table 1. The loading of sulfate on three  $xH_2SO_4/CeO_2$  samples decreased the specific surface area and pore volume in all cases.

Fig. 1 presents the XRD results of ceria-based catalysts. The main peaks were assigned to  $CeO_2$  with the cubic fluorite structure (43–1002) for all samples. The intensity of diffraction peaks for  $xH_2SO_4/CeO_2$  catalysts was weaker than that of  $CeO_2$ , illustrating a loss of crystallinity. Due to the coverage and blockage of pores by sulfates, the specific surface area and crystallinity both decreased in the following sequence:

Table 1 – N <sub>2</sub> catalysts.	physisorption	results of	ceria-based
Catalysts	Specific surface area (m²/g)	Pore diameter (nm)	Pore volume (cm³/g)
CeO <sub>2</sub>	84.39	32.55	0.69
1H <sub>2</sub> SO <sub>4</sub> /CeO <sub>2</sub>	38.20	22.33	0.24
2H <sub>2</sub> SO <sub>4</sub> /CeO <sub>2</sub>	29.63	25.07	0.21
$4H_2SO_4/CeO_2$	32.14	51.52	0.41

 $CeO_2 > 1H_2SO_4/CeO_2 > 2H_2SO_4/CeO_2$ . In addition, low intensity diffraction peaks ascribed to  $Ce_2(SO_4)_3$  (27–0573),  $Ce(SO_4)_2$  (70– 2097) and CeOSO<sub>4</sub> (39–0515) were observed for the  $4H_2SO_4$ / CeO<sub>2</sub> catalyst, indicating the existence of sulfates. The formation of new crystalline phases led to the slightly greater surface area and stronger crystallinity of  $4H_2SO_4/CeO_2$  than  $2H_2SO_4/CeO_2$ . No peaks due to sulfate species were observed over  $1H_2SO_4/CeO_2$  and  $2H_2SO_4/CeO_2$ , which could be due to the small quantity of sulfate species in these samples.

## 2.1.2. H<sub>2</sub>-TPR and O<sub>2</sub>-TPD results

H<sub>2</sub>-TPR experiments was conducted to study the redox properties of ceria-based catalysts and the results are exhibited in Fig. 2a. According to the literature (Lian et al., 2015; Peng et al., 2012), the reduction peaks between 300 and 550°C and between 700 and 900°C for the CeO<sub>2</sub> catalyst can be attributed to the reduction of surface  $Ce^{4+}$  to  $Ce^{3+}$  and bulk  $Ce^{4+}$  to  $Ce^{3+}$ , respectively. A distinctive  $H_2$  reduction peak at 550–650°C was detected over  $xH_2SO_4/CeO_2$ , which was mainly assigned to the reduction of sulfate (Lian et al., 2017; Yang et al., 2013), due to the fact that the  $H_2$  consumption of Ce<sup>4+</sup> was small. It indicates that the catalyst was covered with a substantial amount of sulfate species. With increased sulfate loading on the catalysts, the reduction temperature became higher and the amount of H<sub>2</sub> consumption was larger. Although the amount of reducible species was larger, the reduction temperature for xH<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> was much higher than for CeO<sub>2</sub>. The active temperature window in the NH<sub>3</sub>-SCR reaction was below 500°C. In this temperature range CeO<sub>2</sub> presented stronger redox capability than  $xH_2SO_4/CeO_2$ .

Fig. 1 - XRD patterns of ceria-based catalysts.

Fig. 2 –  $H_2$ -TPR profiles (a) and  $O_2$ -TPD results (b) of  $CeO_2$  and acid-modified  $CeO_2$  catalysts.

 $O_2\text{-}\text{TPD}$  results are shown in Fig. 2b. An  $O_2$  desorption peak ( $\beta$ ) centered at 425°C appears on CeO<sub>2</sub>. As for acid-modified samples, a distinct desorption peak ( $\gamma$ ) is observed in the temperature range of 600–800°C. The  $\beta$  and  $\gamma$  desorption peak are attributed to the oxygen-vacancy adsorbed oxygen and  $O^{2-}$  stripped from lattice oxygen sites, respectively (Ma et al., 2015; Sui et al., 2017). The desorption of surface active oxygen at low temperature indicated that CeO<sub>2</sub> provides a better oxidation environment for NH<sub>3</sub>-SCR of NO than acid-modified samples.

#### 2.1.3. XPS results

The ceria-based catalysts were studied by XPS to understand the chemical states of oxygen present on the surface. Fig. 3 shows the XPS of O 1 s signals. The primary peaks at 528–532 eV were attributed to the lattice oxygen species (denoted as  $O_{\mu}$ ) and the additional shoulder peaks at 532–535 eV were assigned to the surface oxygen species (denoted as  $O_{\alpha}$ ) (Andreoli et al., 2015; Liu et al., 2017a). The relative surface concentration ratios of  $O_{\alpha}/O_{all}$  for the ceria-based catalysts

Fig. 3 – XPS O 1 s results of  $CeO_2$  and acid-modified  $CeO_2$  catalysts.

were also listed in Fig. 3. The  $O_{\alpha}$  ratios increased in the following order:  $CeO_2 < 1H_2SO_4/CeO_2 < 2H_2SO_4/CeO_2 < 4H_2$ .  $SO_4/CeO_2$ . This indicated that there is more abundant surface oxygen on  $xH_2SO_4/CeO_2$ , which is possibly due to the contribution of surface  $SO_4^{2-}$ . The results were in good accordance with the H<sub>2</sub>-TPR results, which show the presence of more reducible species on  $xH_2SO_4/CeO_2$ . However, the oxygen species from surface  $SO_4^{2-}$  presented low oxidation activity, from the H<sub>2</sub>-TPR results.

The XPS spectra in Ce 3d region and the relative ratio of  $Ce^{3+}$  are shown in Fig. S1. The surface  $Ce^{3+}$  ratio on  $CeO_2$  was higher than acid-modified catalysts, which could favor to the formation of surface active oxygen. Therefore,  $CeO_2$  presents stronger redox capability, which is in accordance with the results of  $O_2$ -TPD.

## 2.2. In situ DRIFTS

Fig. 4a presents the DRIFT spectra of NH<sub>3</sub> adsorption on CeO<sub>2</sub> and acid-modified CeO<sub>2</sub> catalysts at 225°C. The surface of the catalysts were covered by several different ammonia species after NH<sub>3</sub> adsorption. The peaks at 1432 cm<sup>-1</sup> were ascribed to the bending vibrations of NH<sup>+</sup><sub>4</sub> on Brønsted acid sites (Liu et al., 2017b; Yu et al., 2017; Zhang and Hou, 2016). The bands assigned to N-H stretching vibration region of coordinated NH<sub>3</sub> on Lewis acid sites were also observed at 3390, 3260 and 3157 cm<sup>-1</sup> (Ma et al., 2016; Zhang et al., 2015b). The negative band at 1362  $\text{cm}^{-1}$  on  $xH_2SO_4/\text{CeO}_2$  derived from the coverage of sulfate species by NH<sub>3</sub>, while the coverage or hydration of part of the residual sulfate species by H<sub>2</sub>O resulted in the negative band at 1385 cm<sup>-1</sup> (Liu et al., 2011). The amount of acid sites increased in the following sequence: CeO<sub>2</sub> < 1H<sub>2</sub>SO<sub>4</sub>/  $CeO_2 < 2H_2SO_4/CeO_2 < 4H_2SO_4/CeO_2$ , indicating that the acidity on CeO2 surface was significantly improved by H2SO4 modification, including Lewis acid sites and Brønsted acid sites. The NH<sub>3</sub>-TPD results also indicated more acid sites of  $1H_2SO_4/CeO_2$  than that of CeO<sub>2</sub> (Fig. S2).

DRIFT spectra of  $NO + O_2$  adsorption on ceria-based catalysts at 225°C are shown in Fig. 4b. When  $CeO_2$  was exposed to  $NO + O_2$ , several bands attributed to nitrate

Fig. 4 – DRIFTs of  $NH_3$  adsorption (a) and  $NO + O_2$  adsorption (b) on ceria-based catalysts at 225 °C.

species were detected, including bridging nitrate (1210 and 1596 cm<sup>-1</sup>), bidentate nitrate (1565 and 1248 cm<sup>-1</sup>) and monodentate nitrate (1534 cm<sup>-1</sup>) (Ma et al., 2016; Zhang et al., 2015a). There were no nitrate species adsorbed on  $xH_2SO_4$ / CeO<sub>2</sub>, in accordance with the NO-TPD results (Fig. S3). The formation of nitrate might be inhibited by the strong acidity of  $xH_2SO_4$ /CeO<sub>2</sub>.

To study the reactivity of adsorbed ammonia species in NH<sub>3</sub>-SCR reaction on  $4H_2SO_4/CeO_2$ , in situ DRIFTS of the reaction between NO +  $O_2$  and pre-adsorbed NH<sub>3</sub> at 225°C were recorded as a function of time (Fig. 5a). The surface was covered with several adsorbed ammonia species after exposure to NH<sub>3</sub>. When introducing NO +  $O_2$ , we can see that the peaks attributed to adsorbed NH<sub>3</sub> species diminished gradually. One band ascribed to H<sub>2</sub>O at 1612 cm<sup>-1</sup> (Lian et al., 2017) was detected at the same time. No nitrate species or other nitrogenous intermediates were observed on the surface during the whole reaction process, indicating an Eley–Rideal reaction mechanism between gaseous or weakly adsorbed NO and adsorbed NH<sub>3</sub> species.

The above results exhibited that no adsorbed  $NO_x$  species formed on  $4H_2SO_4/CeO_2$ , in good accordance with the results shown in Fig. 5b. No bands assigned to adsorbed  $NO_x$  species were observed after  $NO + O_2$  adsorption at 225°C. When ammonia was introduced, bands attributed to  $NH_3$  adsorbed species were detected, including ionic  $NH_4^+$  on Brønsted acid sites (1432 cm<sup>-1</sup>) and N-H stretching vibration bands from coordinated  $NH_3$  (3390, 3260 and 3157 cm<sup>-1</sup>). The results indicated that the reaction between adsorbed  $NO_x$  species and adsorbed  $NH_3$  species did not occur. Therefore, the  $NH_3$ -SCR reaction over the  $4H_2SO_4/CeO_2$  catalyst mainly followed the Eley–Rideal mechanism, similar to the  $CeO_2$ -HF catalyst in literature (Yang et al., 2016).

## 2.3. Catalytic performance

 $NO_x$  conversion over the ceria-based catalysts is exhibited in Fig. 6a. The  $CeO_2$  catalyst exhibited low activity, with a

Fig. 5 – In situ DRIFT spectra of  $4H_2SO_4/CeO_2$  pretreated by exposure to NH<sub>3</sub> followed by exposure to NO + O<sub>2</sub> (a) and pretreated by exposure to NO + O<sub>2</sub> followed by exposure to NH<sub>3</sub> (b) at 225 °C.

Fig. 6 –  $NO_x$  conversion (a) and  $N_2$  selectivity (b) over ceriabased catalysts.

maximum NO<sub>x</sub> conversion of 60% at 330°C. The modification of CeO<sub>2</sub> by H<sub>2</sub>SO<sub>4</sub> led to a remarkable enhancement of NH<sub>3</sub>-SCR activity at 190-440°C. With further increase in the sulfate loading, NO<sub>x</sub> conversion decreased a little at 190-250°C and was enhanced significantly at 250-440°C. 4H<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> showed almost 100% NO<sub>x</sub> conversion at 250–440°C. However, after the deposition of sulfate the catalytic activity over CeO<sub>2</sub> at 140-190°C decreased. The N2 selectivity of ceria-based catalysts is exhibited in Fig. 6b. The N2 selectivity increased with sulfate loading on the ceria-based catalysts. The three xH<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> catalysts all exhibited higher than 90% N<sub>2</sub> selectivity over the whole temperature range that we investigated. 4H<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> also exhibited strong H<sub>2</sub>O and SO<sub>2</sub> resistance (Fig. S4). The introduction of H<sub>2</sub>SO<sub>4</sub> significantly boosted the catalytic performance of  $CeO_2$ , including  $NO_x$ conversion at 190–440°C and N<sub>2</sub> selectivity.

#### 2.4. NO and NH<sub>3</sub> oxidation activity

The separate oxidation activity of NO to  $NO_2$  of the ceriabased catalysts was tested (Fig. 7a).  $CeO_2$  presented the

Fig. 7 – Separate NO oxidation activity (a) and separate  $NH_3$  oxidation activity (b) over ceria-based catalysts.

highest NO oxidation activity. About 50% NO oxidation activity was obtained at 350°C and the oxidation activity decreased at higher temperature, in accordance with the thermodynamic limit (Wen et al., 2007). With the increase of sulfate loading, the NO oxidation activity decreased. The ammonia oxidation activity over ceria-based catalysts is exhibited in Fig. 7b. The separate NH<sub>3</sub> oxidation activity decreased in the following sequence:  $1H_2SO_4/CeO_2 > 2H_2SO_4/$  $CeO_2 > 4H_2SO_4/CeO_2$ , similar to the NO oxidation activity. CeO<sub>2</sub> shows similar NH<sub>3</sub> oxidation activity to that of 2H<sub>2</sub>SO<sub>4</sub>/ CeO<sub>2</sub>. However, the NH<sub>3</sub> oxidation over CeO<sub>2</sub> produced large amounts of NO, NO<sub>2</sub> and N<sub>2</sub>O, compared with xH<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> (Fig. 8). The high temperature activity and N<sub>2</sub> selectivity decreased due to the over-oxidation of NH<sub>3</sub> over CeO<sub>2</sub>. CeO<sub>2</sub> showed high NO oxidation activity but low NH3 oxidation activity, which will be discussed in detail later.

## 3. Discussion

The modification of CeO<sub>2</sub> by  $H_2SO_4$  significantly enhanced the NH<sub>3</sub>-SCR activity at 190–440°C. With further increase in sulfate loading, NO<sub>x</sub> conversion decreased slightly at low temperature (190–250°C) and increased at high temperature (250–440°C). The N<sub>2</sub> selectivity also increased with the sulfate loading on the catalysts.

Previous studies have shown that at low temperatures the redox properties of a catalyst are the key factors governing the reactivity, while at high temperatures the surface acidity plays a crucial role in the NH<sub>3</sub>-SCR reaction (Li et al., 2008; Lietti, 1996; Liu et al., 2006). From the H<sub>2</sub>-TPR results, the onset temperature of H<sub>2</sub> reduction for CeO<sub>2</sub> was much lower than that of  $xH_2SO_4/CeO_2$ . CeO<sub>2</sub> presented much stronger redox capability at low temperature than the sulfate-modified CeO<sub>2</sub> catalysts. Therefore, CeO<sub>2</sub> showed the highest NO oxidation activity. NH<sub>3</sub> oxidation over CeO<sub>2</sub> produced large amounts of  $N_2O$ , NO and  $NO_2$ , leading to the decrease of  $NO_x$  conversion and N<sub>2</sub> selectivity at high temperature. The deposition of sulfate increased the acidity and weakened the redox capability of the catalysts. As a result, the separate NH<sub>3</sub> oxidation and separate NO oxidation activities decreased with the increase of sulfate loading. Therefore,  $NO_x$  conversion and N<sub>2</sub> selectivity increased at high temperature. At the same time, the weaker redox capability at low temperature resulted in lower NO<sub>x</sub> conversion at 140–190°C for  $xH_2SO_4/CeO_2$  than that for  $CeO_2$ .

However, redox capability and acidity are both essential for SCR over ceria-based catalysts in the middle temperature range, such as 190–250°C. From the DRIFTs results, the deposition of sulfate strongly enhanced the acidity of CeO<sub>2</sub>. The presence of more acid sites favors the adsorption and activation of ammonia in NH<sub>3</sub>-SCR reaction and then enhances the catalytic performance. Therefore, the low-temperature NO<sub>x</sub> conversion of CeO<sub>2</sub> at 190–250°C was boosted notably after modification by sulfate. However, further increase in acidity led to a decline in the redox capability based on H<sub>2</sub>-TPR results, and the activity also decreased slightly.

Though  $CeO_2$  showed high NO oxidation activity,  $NH_3$  oxidation activity was low. This might be due to the fact that

Fig. 8 – The products of separate NH<sub>3</sub> oxidation (Fig. 7b) over ceria-based catalysts.

 $CeO_2$  has weak acidity and cannot adsorb and activate  $NH_3$  effectively.

Strong redox capability could lead to the over-oxidation of NH<sub>3</sub> and decrease the NO<sub>x</sub> conversion and N<sub>2</sub> selectivity at high temperature. Strong acidity could enhance the catalytic activity and reduce the over-oxidation of NH<sub>3</sub>. However, an excess of acid sites might cover part of the redox sites and result in a decrease in the low temperatures catalytic activity. Achieving appropriate redox capability and acidity simultaneously will result in an excellent NH<sub>3</sub>-SCR catalyst.

## 4. Conclusions

To study the influence of the acidity and redox capability, CeO<sub>2</sub> catalysts were modified by H<sub>2</sub>SO<sub>4</sub> using an impregnation method for the selective catalytic reduction of NO<sub>x</sub> by NH<sub>3</sub>. A series of xH<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> catalysts all showed significantly better NH<sub>3</sub>-SCR performance than CeO<sub>2</sub> at 190-440°C. CeO<sub>2</sub>, with strong redox capability, showed low NO<sub>x</sub> conversion and N<sub>2</sub> selectivity at high temperature. With the increase of acidity, the high temperature activity and N2 selectivity increased at 250-440°C. The appropriate level of acidity also enhanced the NH<sub>3</sub>-SCR activity at 190-250°C. Too much acid sites could weaken the redox capability and decrease the catalytic activity slightly at low temperature. The proper balance of acidity and redox capability will result in an excellent NH<sub>3</sub>-SCR catalyst. The NH<sub>3</sub>-SCR reaction over 4H<sub>2</sub>SO<sub>4</sub>/CeO<sub>2</sub> mainly followed the Eley-Rideal mechanism, in which adsorbed NH3 species reacted with gaseous or weakly adsorbed NO to finally form N<sub>2</sub> and H<sub>2</sub>O.
